## CCP Working Paper 16-6

### Abstract

This paper uses sales data for ADHD drugs market for the period 2000-2003 and compares estimates of elasticities and merger simulations from three different demand models. Models include logit, random coefficients logit choice model for consumers with heterogeneous tastes, and conditional AIDS demand model in multistage budgeting faced by a representative consumer. The magnitude of cross-price elasticities is large in third model in comparison to the first two, and some of the cross-price elasticities are estimated to be negative. Consequently, hypothetical merger simulations show large price effects for the multistage AIDS model, both for the merging firms as well as for the competitors, in comparison to the other two discrete choice models.

## 1. INTRODUCTION

Competition authorities in the U.S. and Europe are increasingly supplementing traditional merger analysis with quantitative methods involving econometric estimation of demand models and merger simulations. A fundamental issue is to measure market power, typically computed as the price-cost margins  $(p - mc)/p$ , where  $p$  and  $mc$  are price and marginal costs of all related products in a market. While prices can be observed, we do not always have data on marginal costs and so the “new empirical industrial organization” (NEIO) literature suggests estimating a demand system and then inferring markups and marginal costs from those estimates using equilibrium conditions ([Bresnahan, 1989](#)). The intuition of this approach is most easily understood in the context of a monopoly where the first order conditions of the monopolist’s profit maximization problem,  $\max_p pq(p) - c(q(p))$ , gives the familiar relationship at the equilibrium price as  $(p^* - mc(q(p^*))) / p^* = -1/\eta(p^*)$ , where  $\eta(p^*)$  is a scalar measure of the price elasticity of demand. If we can measure the price elasticity of demand, we can infer the mark up. This reasoning extends to oligopoly with multi-product firms, and where the scalar is replaced by a cross-price elasticity matrix. In principle then, the analysis is a straight forward three-step process: use pre-merger data to estimate demand parameters and elasticities, recover marginal costs, and then, simulate a merger via joint profit maximization of products owned by the merging parties to obtain post merger equilibrium prices and markups. For some of the early applications of this technique see [Hausman et al. \(1994\)](#) and [Werden and Froeb \(1994\)](#).

In practice however this is a complicated process as it requires making assumptions and modeling choices along each of the three main steps. For instance, to recover any structural parameters under equilibrium, we must assume a form of competition. Typically it is assumed that the data is from a differentiated products industry where firms are playing a noncooperative price game, i.e., a Nash-Bertrand price model is assumed, but other models, such as quantity competition are also possible.<sup>1</sup> Next, some assumption is needed about the general shape of cost functions and constant marginal costs are often assumed in the relevant range. Further, merger simulations may explicitly account for any gains in efficiency by allowing post-merger costs of the merging parties to be lower by some specified percentage (for a recent review of merger simulation techniques, see [Budzinski and Ruhmer, 2010](#)).

And finally, we need a structure and assumptions about consumer behavior in the industry under study to choose from a menu of different demand models that underlie such a quantitative exercise. Modern demand estimation broadly falls under two class of models: those where a consumer’s utility maximization problem under a budget constraint is either described in the product space, or

---

<sup>1</sup>A somewhat different approach is to use first order conditions that contain a vector of conduct parameters and builds on the theory of ‘conjectural variations’ (see [Corts, 1999](#)).

in the characteristics space, along with an additional constraint that a consumer can only purchase a maximum of one product. In turn, these differences give rise to continuous or discrete choice demand models respectively. A demand model from the first group with several desirable properties is the almost ideal demand system (AIDS) by [Deaton and Muellbauer \(1980\)](#), which allows for a flexible substitution pattern between products. A cost of this flexibility is that the number of parameters that need to be estimated increases with the square of the number of products, and hence data requirements can be quite substantial. Thus estimation is often within the context of multistage budgeting as outlined in [Hausman et al. \(1994\)](#). Alternatively, in the merger simulation context, a ‘proportionality-calibrated’ AIDS due to [Epstein and Rubinfeld \(2001\)](#) is also sometimes used as a merger screening device. In the second class of models, and since the seminal work by [Berry \(1994\)](#), logit and its extensions have been popular in demand estimation with aggregate data. Particularly logit and nested logit are easy to estimate, have a low data requirement, and for that reason may be practical choices in *ex ante* merger analysis ([Ivaldi and Verboven, 2005](#), [Björnerstedt and Verboven, 2016](#)). Nonetheless, they impose a restrictive substitution pattern that suffers from the so called independence of irrelevant alternatives (IIA) problem, albeit it is less severe in the nested logit model. In turn the IIA problem is overcome by allowing for correlations in preferences over attributes that lead to the more general random coefficients logit, or the so-called BLP model attributed to [Berry et al. \(1995\)](#).

In this paper we focus on this last aspect, the choice of demand systems, and show differences in estimated elasticities and post-merger simulated prices when demand is estimated using alternative but popular models on the same aggregate sales data. However, we estimate these models where some of the products may in fact be complements, and show that the choice of demand models may lead to very different estimates of elasticities and of post-merger price predictions.

Discrete choice models force substitution patterns among products to be positive, i.e., all products are gross substitutes due to the assumption that a consumer can choose only one product.<sup>2</sup> By comparison, demand models estimated in the product space do not impose this restriction and can give rise to cross-price elasticities that are positive, negative, or a combination. However, they are generally estimated with less precision if there is not enough price variation and/or if there are too many products. In turn these differences in substitution patterns may be important for estimating

---

<sup>2</sup>When there are complementarities or bundling, discrete choice models on aggregate data can still be employed by removing the constraint that a consumer must buy only one product. [Nevo et al. \(2005\)](#) provide an example of a random coefficients logit model where individual libraries buy all journals above a threshold until they exhaust their budget. Alternatively, consumer choice can be modeled as A, B or A&B (and similar other combinations) for multiple choices when products are bundled together. [Lucarelli et al. \(2010\)](#) use discrete choice methods to handle such combinations in the context of choice of cancer drugs. However, to model the combined choice of A&B relative to A and B individually, one either needs data on individual choices so as to construct shares of A&B relative to A or B alone, or other assignment rules, as was the case for [Lucarelli et al. \(2010\)](#) that allow a researcher to allocate total observed sales of A and B to shares of A, B and A&B.

---

marginal costs and mark-ups for merger simulations. For instance, in the case of drugs, products that seem to be substitutes, e.g. drugs within the same therapeutic class but differing by active ingredient/molecule or by formulation may in fact be jointly consumed by some patients to form a complete therapy regime. In the analgesics markets, patients sometimes combine or stagger 6-8hr dosages of ibuprofen (Advil or Morten) with acetaminophen (Tylenol) to get pain relief over the course of the day. Thus, such drugs may be gross complements rather than substitutes. Estimating a discrete choice model, even a sophisticated one that overcomes the IIA problems, may still be committing a specification error.

The choice of demand models in merger simulations has been highlighted in the literature, but in the context of substitute goods, i.e., when the cross-price elasticities are positive. For instance, [Crooke et al. \(1999\)](#) use monte carlo methods to generate data that equate equilibrium prices, quantities and elasticities across four different demand models (AIDS, logit, linear and log-linear) and use the specified demand parameters to predict post merger prices. They find that log-linear, followed by AIDS models, gives the largest predicted post merger prices. In a similar vein, [Huang et al. \(2008\)](#) also use monte carlo methods to generate data sets that correspond to each of the four demand models above, but where data is calibrated so as to have the same elasticity matrix at equilibrium prices. Since they include logit as one of the models, which can only have positive cross-price elasticities, their calibration and model comparisons are in the context of substitute goods. In this respect they incorporate estimating the ‘wrong’ model, i.e., a specification error since data generation may be from logit demand system while the estimated model may be AIDS or vice versa. Thus the effect of mis-specification of demand model is only tested in the magnitude but not the sign of the underlying substitution patterns. The authors find that the magnitude of the bias in the estimated elasticities varies by the type of model, but that the logit model gives the best results in terms of merger predictions, even when the true data generating process matches one of the other demand models.

Finally, and most closely related to this paper, [Weinberg and Hosken \(2013\)](#) use real pre- and post-merger data from two product markets (breakfast syrup and motor oil) where a handful of substitute goods were available, and a merger was observed in each case. They investigate differences in predicted post-merger prices based on linear, AIDS and two variants of logit models and also compare the predictions to the actual post-merger prices. The authors report that generally the models under-predicted the change in prices for the motor oil market, where true price changes were large, but over predicted change in prices for the breakfast syrup market, where the true price changes were negligible. Moreover, they find that the magnitude of predicted price change for the AIDS model was larger than for the logit models.

---

While there are many aspects to consider when choosing among different demand models, in this paper we highlight the role of complementary goods and the estimated elasticity matrix. In comparison to the studies above, we use aggregate sales data on psychostimulant drugs prescribed for treating symptoms of attention deficit hyperactivity disorder (ADHD), which differ by active ingredient (molecule) and formulation (tablet, suspended release, extended release etc.), and while these drugs appear to be substitutes, some of them may be gross complements. To see why, note that ADHD is primarily an adolescent disease where children suffering from the disorder are often prescribed psychostimulant drugs to help them cope with symptoms of ADHD during school hours, as well as provide some coverage in the late afternoon/early evening. Differences in formulation imply differences in absorption rates of the drug in the body, and hence differences in the effectiveness period of the drugs; four hours, six-eight hours, or twelve hours (Conner, 2006). Thus, even though two drugs with the same active ingredient produced either by the same firm or by two competitors may at first pass appear to be substitutes, they can in fact be used in combination, where an 8-hr drug can be taken in the morning before going to school, and followed up with a 4-hr formulation after school to provide coverage throughout the working day. For some patients, the 8-hr/4-hr combination would be a complement, and may be a substitute for the more expansive once a day 12-hr drug.

Consequently, for this data we estimate demand parameters from logit and random coefficients logit models, and compare the results from AIDS model with multistage budgeting. Specifically, comparisons across the models are made on the basis of estimated elasticity matrices and changes in implied prices under hypothetical merger simulations. All three models are estimated using standard techniques for that class of models. The AIDS model is estimated with multistage budgeting using techniques highlighted in Hausman et al. (1994), and we follow the methodology outlined in Nevo (2000b) to estimate the logit and the random coefficients logit (BLP) models. The current data was used previously in a different context in Bokhari and Fournier (2013), and as our point of entry, we use multilevel AIDS parameters from that paper. For the random coefficients logit we model deviations from mean utility for a consumer based on her simulated demographics and a random taste parameter that affects her marginal utility of price and other product characteristics, particularly molecule and form of the drug. Further, in all models, price is treated as an endogenous variable and the same set of instruments are used to correct for the endogeneity bias so as to put all three models on equal footing. Specifically, we use the ‘Hausman instruments’, i.e., after controlling for market fixed effects, the price of a drug from another geographic market is used as an instrument for the price in the current market.<sup>3</sup>

---

<sup>3</sup>The use of such instruments has been criticised in the literature, most famously by Bresnahan (1997), and certainly the estimates given here may also be subject to potential common demand side shocks criticism, but the point here is that the same price instruments are used in all three models so as to be able to compare them.

---

The substitution patterns, and the corresponding merger simulations from the three models give strikingly different results. At first pass, demand estimates from the random coefficients model appear to be reasonable, especially in comparison to the logit model, as they overcome the IIA restrictions. Also, (mean) own price elasticities are greater than one in magnitude, and cross-price elasticities are positive, which they should be if these drugs are substitutes. However, these results are at odds with those from the AIDS model where several drugs appear to be gross complements, and cross-price elasticities are much larger in magnitude, including for those drugs that are estimated to be substitutes. This complementarity result is robust to several alternative specifications of the AIDS model and does not appear to be simply due to an aggregation bias in the data. Further, the estimated complementarity makes intuitive sense as it appears among very specific drugs: those within the same molecule but differing by formulation and coverage described above, but not across different molecules.<sup>4</sup>

Insights from this paper also provide a potential explanation for merger results reported in [Björnerstedt and Verboven \(2016\)](#). They use nested logit models to predict post-merger prices in the Swedish analgesics market, and compare them to observed prices post an actual merger. The authors report that while overall the simulations were quite successful in terms of closeness between predicted and true price changes, nonetheless the simulations slightly under-predicted the price increase for the merging firms, and significantly under-predicted the price increase by the non-merging competitors. Following on from that, we allow for three hypothetical mergers (between two small firms, a small and large firm, and between two large firms) based on the estimated elasticities from the three models estimated for the ADHD drugs data. We find that post-merger predicted price changes are on average nearly one order of magnitude larger under AIDS estimation compared to the predictions via the random coefficients logit model. Further, we also find that predicted price increase for the hypothetical merger for some of the non-merging competitors is considerably larger under AIDS than for the other two models. Thus, we conjecture that the differences between true and predicted price changes observed in the Swedish analgesics market may be due to the underlying complementarity between some drugs that the discrete choice model for aggregate sales cannot identify.

---

<sup>4</sup>An aggregation bias could arise when different members of a household purchase alternative products over the same purchase period, for instance regular pancake syrup for some members of the household and light pancake syrup for those with diabetes. While light and regular syrups may be unrelated in demand for individuals, they would appear as complements in aggregate data. In our case of ADHD drugs, it would be if either multiple household members were diagnosed with ADHD, and using different drug therapies, or since our data is aggregated over a year, if the same individual was using alternative drugs during different parts of the year. While drug switches do happen soon after the initial diagnosis, so as to identify the right molecule for the person vis-a-vis the effectiveness of the main molecule and any side effects, once the correct drug is identified, it is difficult to imagine why the form would be different at different points in the year for the same individual. Nonetheless, aggregation bias cannot be completely ruled out.

---

The rest of the paper is organized as follows. The next section describes the product market and the data. Section three provides a brief overview of demand models and specification of the models estimated in this paper. Section four contains three types of results: selected regression coefficients, elasticity matrices, and simulated price changes under hypothetical mergers from each of the three demand models and for three different hypothetical mergers. The last section concludes.

## 2. DATA AND CONTEXT

We use retail level sales data from the U.S. for psychostimulant drugs used for the treatment of attention deficit hyperactivity disorder (ADHD). ADHD is a commonly diagnosed disorder among children and approximately 9.5% of all school aged children were diagnosed with this disorder in 2003, of which 60% were on some form of medication for treatment (see [Bokhari and Schneider, 2011](#)). Children with ADHD are believed to have abnormal functioning of two key neurotransmitters, dopamine and norepinephrine, which affect attention and activity. Psychostimulant drugs, which consist of various molecules such as methylphenidates or amphetamines help with regulation of these neurotransmitters either by preventing the reabsorption into cells, or by promoting the release of these chemicals from the brain. Physicians and patients have to experiment with different molecules to identify which one is most suitable for a given patient, and to rule out those that induce adverse reactions. Ritalin, the most well known ADHD drug, consists of active ingredient methylphenidate-HCL (MPH), and was originally patented in 1954 by Ciba Pharmaceutical for the treatment of chronic fatigue, depression, and narcolepsy, as well as to offset the sedating effects of other medications (currently the drug is produced by Novartis). The patent for the original drug is long expired, and several firms now provide generic versions of Ritalin. Additionally, several other molecules and forms have since then been approved by the Food and Drug Administration (FDA) agency for the treatment of ADHD, and some of those are still on patent. These drugs are differentiated not just by the main active ingredient/molecule, but also by the specific form of the drug. Within each molecule, drugs are available as immediate-release (IR) or extended-release (ER) forms, where the main difference is in absorption rates, time to peak effects, and importantly, how many times a day the drug needs to be administered as some have a 4-hour effect, and typically need to be taken up to three times a day, while others can last 8 or 12 hours and require fewer dosing regimes per day.

The data set used in this analysis consists of annual sales (quantities and revenues) between 2000 and 2003 of all ADHD drugs, and was drawn from NDCHealth's proprietary Source Territory Manager files. Quantity is provided by weight (total number of pills times the strength in milligrams of the active ingredient), and revenue is the nominal dollar value received by all pharmacies in a ZIP code for a given drug from all payers (copay plus any third party payments such as via insurance). Data

---

was aggregated up to the county level, all dollar values were converted to constant 2000 dollars using the CPI, and price was derived as revenue divided by quantity. The analysis is restricted to counties in 778 metropolitan statistical areas as zero sales were often observed in rural counties.

TABLE 1. Average Prices and Shares

Product	Firm	2000			2003		
		Price	Share (Rev)	Share (Qty)	Price	Share (Rev)	Share (Qty)
<u>MPH-IR (~4hrs)</u>							
1-Ritalin (1.0)	Novartis	47.99	0.081	0.056	52.41	0.009	0.010
2-Methylin (1.0)	Mallinckrodt	37.68	0.068	0.058	31.81	0.013	0.023
3-Generic MPH-IR (1.0)	19 firms	37.40	0.185	0.163	33.06	0.026	0.046
<u>MPH-ER (~8hrs)</u>							
4a-Ritalin SR (0.83)	Novartis	66.56	0.032	0.016	76.44	0.003	0.002
4b-Ritalin LA (1.25)	Novartis	.			57.25	0.024	0.025
5a-Metadate CD (1.25)	Celltech	.			56.22	0.024	0.024
5b-Metadate ER (0.83)	Celltech	65.33	0.007	0.003	66.11	0.002	0.002
6-Methylin ER (0.83)	Mallinckrodt	58.41	0.004	0.002	52.29	0.006	0.007
7-Generic MPH-ER (0.83)	15 firms	52.78	0.080	0.051	48.12	0.008	0.009
<u>MPH-XR (~12hrs)</u>							
8-Concerta (0.69)	Ortho-McNeil	110.33	0.047	0.014	96.45	0.261	0.158
<u>MAS-IR (~4hrs)</u>							
9-Adderall (2.86)	Shire	19.86	0.311	0.497	31.87	0.029	0.053
10-Generic MAS-IR (2.86)	3 firms	.			26.52	0.076	0.164
<u>MAS-XR (~12hrs)</u>							
11-Adderall XR (2.14)	Shire	.			52.58	0.238	0.259
<u>DEX-IR (~4hrs)</u>							
12-Dexedrine (1.75)	Glaxo Smith Kline	27.36	0.010	0.012	34.94	0.002	0.003
13-Dextrostat (1.75)	Shire	23.59	0.018	0.024	23.25	0.002	0.004
14-Generic DEX-IR (1.75)	4 firms	.			24.62	0.004	0.009
<u>DEX-ER (~8hrs)</u>							
15-Dexedrine SR (2.14)	Glaxo Smith Kline	32.08	0.062	0.063	40.25	0.007	0.010
16-Generic DEX-ER (2.14)	2 firms	.			35.14	0.011	0.018
<u>OTH</u>							
17a-Cylert (0.44)	Abbott Laboratories	85.89	0.023	0.009	90.06	0.002	0.001
17b-Provigil(0.28)	Cephalon, Inc	79.13	0.059	0.025	89.85	0.094	0.061
17c-Generic Pemoline (0.44)	8 firms	64.76	0.015	0.008	60.49	0.004	0.004
17d-Strattera (0.83)	Eli Lilly	.	.	.	83.59	0.156	0.108

**Notes** Prices are per unit of defined monthly dosage (DMD). The number in parenthesis in front of the name of the drugs is the conversion factor used for converting to generic MPH-IR equivalent dosage.

Table 1 lists the names, manufacturers, and classifications (molecules and forms) of all ADHD drugs that were on the market during the study period. By 2003 there were 16 branded products available in the market along with generics for many expired patents, spanning across three main molecules: methylphenidate-HCL (MPH), mixed amphetamine salts (MAS), and dextroamphetamines (DEX). Two other molecules (pemoline and provigil) are not first line ADHD drugs while another, (atomoxetine, brand name Strattera) is an FDA approved ADHD drug but is a non-stimulant and

introduced in the last year of the data series. These last three molecules are categorized as ‘other’ (OTH) molecules in the table. Within each molecule, drugs are sub-grouped based on their forms IR, ER and XR which roughly correspond to hours coverage by a the given drug (4, 6-8 or 12 hours). For instance, a tablet of Ritalin, listed as MPH-IR, typically provides coverage of 4 hours while Concerta, also in the same molecule but different form (MPH-XR), provides a 12 hours coverage.

Note that these drugs cannot be substituted on a gram-for-gram basis, especially those is different sub-groups, and hence some dosage equivalence is needed so that one can compare price per dosage across different drugs rather than price per gram. For instance, a child who is taking 100mg of Concerta over a period of time, if switched to Ritalin (MPH-IR) would have a change in dosage to 69mg over the same period, and hence it makes sense to compare price of 100mg of Concerta to price of 69mg of Ritalin rather than to 100mg of Ritalin. The dosage conversion factors to MPH-IR are given in parenthesis in front of the name of drug. Using dosage conversion factor between MPH-IR and other drugs, and World Health Organization’s (WHO) definition for defined daily dosage (DDD) for MPH-IR (30mg as DDD or 0.9 grams per month), we have converted the total quantity for any given drug to defined monthly dosage (DMD). Thus if total quantity of Concerta sold in a year is X grams, it becomes  $(.69X/.9)$  DMD. Similarly, average price of Concerta, which in 2003 was \$73.94 per gram (in constant 2000 dollars) becomes  $73.94 \times .9 / .69 = \$96.45$  per DMD (in 2000 constant dollars). Table 1 provides the average price and shares by revenue and quantity (post DMD adjustment) for two selected years.

Due to some data limitations, in the analysis that follows we treat certain drugs as one combined product. Within each molecule-form combination, generic drugs by different manufactures are treated as one combined product. For instance, in 2003 there were 19 separate manufactures for the generic version of MPH-IR (i.e., generic version of Ritalin), and we combine the sales data from these different generic producers and treat them as one product. There are two reasons why generics within a molecule-form are treated as one product. First, individual manufactures for generics are identifiable in this data series for only the last two years, and treating these products as sperate would significantly limit the number of useable observations (from four years to two years). Second, within a specific market (county-year), collectively the generics have positive sales, but individually several products have zero sales – in 2003 the average share of the 19 MPH-IR generics collectively was 2.6% but individually in any given county many had zero sales. Since price is computed as revenue divided by quantity, price of an individual generic product cannot be ascertained for that county-year. This poses a serious estimation challenge for product space based models, such as AIDS specification, where share of a product in a market is a function of not only own price, but price of *all* other other products. Just to be clear, treating generics separately implies that the share equation for Ritalin would need to be specified as a function of own price, price of 15 other

---

branded products, and price of 49 ( $=15+19+3+4+8$ ) generics. If the price of even a single generic is not available for the county-year combination (since sales for it were zero in that county-year), then no data from that county-year can be used in the analysis (and may lead to sample selection problems). Combine that with the earlier mentioned limitation of total two years of identifiable generic manufactures, and estimation is nearly impossible.

Note also that this issue of unknown price when quantity/share is zero in a county-year is equally problematic in discrete choice methods. For instance, in a logit specification, share is a function of own price and not the price of other products, but a county-year market has as many ‘observations’ (share-price combinations) as the number of products (think of data set in ‘longform’). This means that if the price is unknown, the share-price combination is not available for that county-year, and hence the total length of the panel is varying not due to varying choice set per market, which would be fine if the specific generic was not available in the market, but is changing because no one purchased that drug even though it is available and correct estimation would require zero share with a positive known price.

For somewhat similar reasons, we treat Novartis’s Ritalin SR and Ritalin LA as one drug and Celltech’s ER and CD as one drug (Novartis phased out SR tablet and introduced LA capsule and Celltech used a similar strategy). Finally drugs listed as ‘OTH’ are also treated as one product so that the final data set used for the alternative demand estimation analysis consists of 17 different products.

### 3. MODEL SPECIFICATION

**3.1. Overview of Demand Models.** Earlier empirical work involving demand models used product space approach, and focused on specifying demand systems that were consistent with the utility maximization problem of a representative consumer, met the requirements for aggregating over consumers, and allowed for flexible substitution patterns between products. Typical models include the Linear Expenditure System (Stone, 1954, Barten, 1964), the Rotterdam model (Theil, 1965), the Translog model (Christensen et al., 1975), and the Almost Ideal Demand System (AIDS – Deaton and Muellbauer, 1980), each with varying degree of flexibility in the substitution patterns. However, a common difficulty in product space approach is the dimensionality problem: unless a restrictive form is used, the number of demand system parameters increases in the square of the number of products and estimation requires access to a very rich data set. To reduce the dimensionality problem, Hausman et al. (1994) relied on weakly separable preferences of a representative consumer, along with other assumptions necessary to allow for a multistage budgeting, to specify a series of demand systems at different levels. This method, which has become popular in empirical

---

industrial organization, involves estimating a multilevel system consisting of, for instance, top, middle, and bottom level demand systems. The top level consists of an overall demand for the segment (e.g. beer) while the middle and bottom levels specify flexible forms such as AIDS or cobb-douglas demand equations for subgroups of products (foreign, domestic, premium beers etc.) and then for individual brands (Miller Lite, Coors, Budwiser, etc.). Some recent applications include [Ellison et al. \(1997\)](#), [Hausman and Leonard \(2002, 2005\)](#), [Chaudhuri et al. \(2006\)](#) and, [Bokhari and Fournier \(2013\)](#). Alternatively, the distance metric approach developed in the spatial model by [Pinkse et al. \(2002\)](#) offers an alternative to multistage budgeting for handling a large number of parameters by specifying the cross-price coefficients as function of distance between brands in the product space. [Pinkse and Slade \(2004\)](#) extend the method and apply it to the UK brewing industry while [Rojas \(2008\)](#) applies this method on the AIDS demand specification of the US beer industry.

While the product space is more natural in the sense that consumers have preferences over products, the characteristics space approach due to [Lancaster \(1966\)](#) and [McFadden \(1973\)](#), and later further developed by [Berry \(1994\)](#) in the context of aggregate demand, views products as bundles of characteristics over which consumers have defined preferences. Consumers (indirect) utility is defined as a function of a few relevant characteristics of the product (some of which are not observed by the econometrician), price and an idiosyncratic random error term. The characteristics approach avoids the dimensionality problem since the parameters to be estimated do not increase in the square of the number of products, or even by the number of products if the dimension of relevant characteristics does not increase with the number of brands. Further when the error term in the consumer's random utility model is specified as a Type 1 extreme value that is independently and identically distributed, it leads to the famous logit model but introduces the independence of irrelevant alternatives (IIA) problem attributed to lack of correlations in consumer preferences over products. Allowing for correlations among groups of products, or more generally among preferences over attributes, leads to the nested logit and the random coefficients model, where the latter is also known as the BLP model ([Berry et al., 1995](#), [Cardell, 1997](#)). Early applications as well as important extensions with aggregate sales data include [Verboven \(1996\)](#), [Nevo \(2000a, 2001\)](#), [Sudhir \(2001\)](#), [Ivaldi and Verboven \(2005\)](#), [Petrin \(2002\)](#) and [Grigolon and Verboven \(2014\)](#) among others. Despite the estimation difficulties associated with the BLP model, such as the role of starting values in non-linear search algorithms, choice of alternative optimization methods, accuracy of contraction mapping to invert market shares, integration to obtain market shares, and under-identification of variance parameters for the random components, random coefficients model has become the favorite workhorse of much of modern demand estimation (see [Knittel and Metaxoglou \(2014\)](#), [Dubé et al. \(2012\)](#), [Skrainka and Judd \(2011\)](#) and [Moon et al. \(2014\)](#), respectively for advancements in work related to the aforementioned issues).

---

**3.2. Model 1: Standard Logit/Homogenous Tastes.** The logit assumes that there is no variation in tastes across patients and hence the indirect utility for consumer  $n$  for product  $j$  in market  $t$  (county-year combination) is given by

$$\begin{aligned} u_{njt} &= \alpha_n(y_n - p_{jt}) + \mathbf{x}_{jt}\boldsymbol{\beta}_n + \xi_{jt} + \epsilon_{njt}, \text{ where} \\ n &= 1, \dots, N, \quad j = 0, 1, \dots, J, \quad t = 1, 2, \dots, T \text{ and where} \\ \boldsymbol{\beta}_n &= \boldsymbol{\beta}, \quad \alpha_n = \alpha, \quad \text{for all } N. \end{aligned} \quad (1)$$

Note that homogenous tastes are due to the assumption that  $\boldsymbol{\beta}_n = \boldsymbol{\beta}$  and  $\alpha_n = \alpha$  for all  $N$ . In the equation above, 0 refers to the ‘outside good’, chosen when the patient does not purchase any of the products. The vector  $\mathbf{x}_{jt}$  (of dimension  $k - 1$ ) and random variable  $\xi_{jt}$  are the observed and unobserved (to the econometrician) product characteristics that do not vary over consumers. The former consists of molecule and form of the drug (in our case  $k - 1 = 6$ ), while the latter is a scalar index due to pack variety, expiration date or other unobservable characteristics related to quality.<sup>5</sup> The utility function in (1) can be written compactly as

$$u_{njt} = \alpha y_n + \delta_{jt} + \epsilon_{njt}, \quad (2)$$

where  $\delta_{jt} \equiv \alpha(-p_{jt}) + \mathbf{x}_{jt}\boldsymbol{\beta} + \xi_{jt}$  is the mean utility for product  $j$  in market  $t$ . For the logit model, we assume that  $\epsilon_{njt}$  are independently and identically distributed (iid) and follow a Type-1 extreme value distribution given by  $F(\epsilon) = \exp(-\exp(\epsilon))$ . In this case, the market share of product  $j$  is

$$s_{jt}(\boldsymbol{\delta}_t) = \int_{\mathbb{A}_{jt}} dF(\boldsymbol{\epsilon}) = \frac{\exp(\delta_{jt})}{\sum_{j=0}^J \exp(\delta_{jt})} \quad (3)$$

where  $\mathbb{A}_{jt}$  is the set of characteristics of individuals that choose brand  $j$  in market  $t$ . The outside option (described below) is normalized by assuming that the price and other characteristics are zero for product 0 (i.e.,  $u_{n0t} = \alpha y_n + \epsilon_{n0t}$  and  $\delta_{0t} = 0$ ) and hence the share equation can be transformed so that

$$\ln(s_{jt}) - \ln(s_{0t}) = \delta_{jt} \equiv \alpha(-p_{jt}) + \mathbf{x}_{jt}\boldsymbol{\beta} + \xi_{jt} \quad (4)$$

can be estimated using linear regression methods. Given estimates of model parameters  $\boldsymbol{\theta}_1 = [\alpha \ \boldsymbol{\beta}']'$ , elasticity of product  $j$  with respect to price of product  $k$  in market  $t$  can be computed as

$$\eta_{jkt} = \frac{\partial s_{jt}}{\partial p_{kt}} \frac{p_{kt}}{s_{jt}} = \begin{cases} -\alpha p_{jt}(1 - s_{jt}) & \text{if } j = k, \\ \alpha p_{kt} s_{kt} & \text{otherwise.} \end{cases} \quad (5)$$

For markets where the outside good has a large share (so that  $1 - s_{jt}$  is small), this makes the own price elasticity to be nearly proportional to the price of the product. Also, the cross-price elasticity

---

<sup>5</sup>There are four molecules and three forms, each of which is specified as a dummy variable. Thus, with three dummies for molecules, two for the form, and one intercept,  $k - 1 = 6$ . Also, we write the dimension of vector  $\mathbf{x}_{jt}$  as  $k - 1$  because later we subsume the price variable in the matrix  $\mathbf{X}$  which then has  $k = 7$  columns.

of product  $j$  with respect to product  $k$  depends only the market share of  $k$ , and not of all other products, i.e., it exhibits the IIA property.

**Outside Good.** To estimate the model in (4), we need a measure of  $s_0$ , i.e., share of the outside good. In 2003, approximately 9.5% of school aged children (age groups 4-19 years) were diagnosed with ADHD, along with a much smaller percentage of adults, and of these approximately only 60% were on ADHD medication. Thus we take total consumption of all ADHD drugs in a given market, and divide it by  $.1 \cdot .60$  times the number of school aged children in that market to compute an approximate consumption rate. Next, to compute the *potential* size of the market, we assume that all of the diagnosed children (i.e., 100% of the 10% diagnosed), plus an additional 1% of the adult population are candidates for drug therapy, and multiply the rate above with this candidate population. In terms of quantity, this gives the (potential) market size to vary from 2.01 to 2.90 times the observed total consumption in each county, with an average value of 2.23 times the total consumption. Given the potential size of the market  $M_t$ , then based on the observed values of  $q_{1t}, \dots, q_{Jt}$ , the shares of the ‘inside’ goods  $s_{1t}, \dots, s_{Jt}$  are defined relative to this value as

$$s_{jt} = q_{jt}/M_t \quad j = 1, \dots, J \text{ for all } t = 1, \dots, T \quad (6)$$

and hence the share of the outside good per market is just  $s_{0t} = 1 - \sum_{j=1}^J s_{jt} \forall t$ . This sets the average outside share to 55.08% and varies between 50.33% and 65.54% across the markets. For robustness checks, we repeated the calculation above but assumed that the true prevalence of ADHD among children is 15%, i.e., an additional 5% are undiagnosed and that all of them could potentially be prescribed ADHD medication plus the 1% of adult population. This increased the average share of the outside good to 67.33% and that of the average market size to 3.06 times the total consumption.<sup>6</sup>

**Brand Dummies and Price Instruments.** The error term in (4) is likely to be correlated with the prices so that  $\text{cov}(p_{jt}, \xi_{jt}) \neq 0$  and hence as a first step towards consistent estimation, we estimate a

---

<sup>6</sup>We also computed the potential size and share of outside good in a very different manner but it led to such extreme values of potential market and share of outside good that we did not use this alternative definition in our final analysis but report it here briefly. We used a 12-hr (day-long) coverage of a standard dose of ADHD drug multiplied by candidate population in each area as the total potential size of the market. According to WHO, a standard dose is a 30mg pill of MPH-IR (i.e., immediate release tablet of methylphenidate such as Ritalin), and if taken three times a day it would provide a 12-hr coverage. Thus a standard dose is 90mg of MPH-IR per day per person or 10.8 grams per year. We multiplied this dose with 15% of all school aged children and 1% of adult population to compute the market size. If we reduce the population percentages, it produces potential market size to be smaller than observed quantity in some markets (there is large cross-sectional variation in actual consumption rates and indeed even in diagnosis). However keeping it at this value of population produces a share of outside good that varies from 18.55% to 99.76% with an average value of 90%, and of market size that varies between 1.23 to 417.38 with an average value of 18.59 times total consumption. Results from such an extreme potential size market definition are available upon request, but briefly, while they don’t change the regression coefficients or estimates of own-price elasticities by much, they make the cross-price elasticity estimates smaller by an order of magnitude (see formula for logit price elasticities to see why). Following on from that, merge simulations also show considerably smaller impact on price changes for competitors’ products.

---

fixed effects model with dummies for individual products and markets so that the equation becomes  $\ln(s_{jt}) - \ln(s_{0t}) = \delta_{jt} = \alpha(-p_{jt}) + \mathbf{x}_{jt}\boldsymbol{\beta} + \xi_j + \xi_t + \Delta\xi_{jt}$ , where  $\xi_j$  is the brand fixed effect and  $\xi_t$  is the market fixed effect. Since brand characteristics (molecule and form) do not change by individual markets, those variables are dropped in favor of the brand dummies. Market fixed effects are proxied with linear and quadratic time variables and dummies for state variables.

Once brand specific dummy variables are included in the regression, the error term is just the market specific deviation from the mean of the unobserved characteristics, for instance local level variation in pack variety or local promotions, and may still require the use of instruments for price if  $E(\Delta\xi_{jt}p_{jt}|\mathbf{x}_{jt}) = 0$  does not hold. Thus, we use instruments originally due to [Hausman et al. \(1994\)](#). They use the panel nature of data and the assumption that prices in different areas are correlated via common cost shocks, to use a price vector from other city as instrument for the price vector in a given city. The identifying assumption is that after controlling for brand specific intercepts and demographics, the city specific valuations of a product are independent across cities but may be correlated within a city over time. Given this assumption, the price of a brand in another city is a valid instrument, so that price of brand  $j$  in two cities will be correlated due to the common marginal cost, but due to the independence assumption will be uncorrelated with the market specific valuation of the product. Since our data is at county level, we use the average price of a given drug from 20 randomly selected counties that are not from the same census region as the original county (so as to minimize the possibility of common demand side shocks).

**3.3. Model 2: Random Coefficients Logit/Heterogenous Tastes.** We now turn to the heterogenous consumer, where the general set up of utility for consumer  $n$  for product  $j$  in market  $t$  is as in (1), but without imposing the restriction that taste parameters  $\{\alpha, \boldsymbol{\beta}\}$  – the marginal utilities of product characteristics – are the same for all consumers. Instead each consumer is assumed to have a different set of coefficients  $\{\alpha_n, \boldsymbol{\beta}_n\}$  which are modeled as a function of underlying common parameters  $\{\boldsymbol{\Pi}, \boldsymbol{\Sigma}\}$  that are multiplied to the person specific characteristics  $(\mathbf{d}_n, \boldsymbol{\nu}_n)$ . These include observable demographic information as well as other unobservable characteristics such as physiology, type of ADHD, and school circumstances (e.g. presence of a school nurse that can administer medication during school hours if a child is taking multiple doses of 4-hr drugs within a day) that may effect the choice of drug. Thus  $(\mathbf{d}_n, \boldsymbol{\nu}_n)$  are random draws from a mean zero population with distribution functions  $F_d(\mathbf{d})$  and  $F_\nu(\boldsymbol{\nu})$ , and

$$\begin{bmatrix} \alpha_n \\ \boldsymbol{\beta}_n \end{bmatrix} = \underbrace{\begin{bmatrix} \alpha \\ \boldsymbol{\beta} \end{bmatrix}}_{\boldsymbol{\theta}_1} + \underbrace{\boldsymbol{\Pi}\mathbf{d}_n + \boldsymbol{\Sigma}\boldsymbol{\nu}_n}_{\boldsymbol{\theta}_2 = \{\boldsymbol{\Pi}, \boldsymbol{\Sigma}\}}. \quad (7)$$

The person specific coefficients are equal to the mean value of the parameters  $\boldsymbol{\theta}_1 = [\alpha \ \boldsymbol{\beta}']'$ , plus deviation from the mean due to a second set of parameters  $\boldsymbol{\theta}_2 = \{\boldsymbol{\Pi}, \boldsymbol{\Sigma}\}$  and given by  $\boldsymbol{\Pi}\mathbf{d}_n + \boldsymbol{\Sigma}\boldsymbol{\nu}_n$ . Note that  $\boldsymbol{\Pi}$  is  $k \times D$  matrix of parameters and  $\boldsymbol{\Sigma}$  is  $k \times k$  matrix of parameters.

If we insert (7) back into (1) and simplify, then the utility function can be decomposed into three parts (or four, if we count  $\alpha_n y_n$  term but that drops out later on) and can be written as

$$\begin{aligned} u_{njt} &= \alpha_n y_n + \delta_{jt} + \mu_{njt} + \epsilon_{njt} \quad \text{where,} \\ \delta_{jt} &= \delta(\mathbf{x}_{jt}, p_{jt}, \xi_{jt}; \boldsymbol{\theta}_1) = \alpha(-p_{jt}) + \mathbf{x}_{jt}\boldsymbol{\beta} + \xi_{jt} \\ \mu_{njt} &= \mu(\mathbf{x}_{jt}, p_{jt}, \mathbf{d}_n, \boldsymbol{\nu}_n; \boldsymbol{\theta}_2) = (-p_{jt}, \mathbf{x}_{jt})(\boldsymbol{\Pi}\mathbf{d}_n + \boldsymbol{\Sigma}\boldsymbol{\nu}_n). \end{aligned} \quad (8)$$

As before,  $\delta_{jt}$  is the mean utility of drug  $j$  and is common to all patients, and  $\mu_{njt} + \epsilon_{njt}$  is the mean-zero heteroscedastic error term that captures the deviation from the mean utility. The market share of product  $j$  is the integral of the joint distribution of  $(\mathbf{d}, \boldsymbol{\nu}, \boldsymbol{\epsilon})$  over the mass of individuals in region  $A_{jt}$ ,

$$s_{jt} = \int_{A_{jt}} dF(\mathbf{d}, \boldsymbol{\nu}, \boldsymbol{\epsilon}) = \int_{A_{jt}} dF_d(\mathbf{d})dF_\nu(\boldsymbol{\nu})dF_\epsilon(\boldsymbol{\epsilon}) \quad (9)$$

where the second part follows only if we assume that the three random variables for a given consumer are independently distributed. If we continue to assume that  $\epsilon_{njt}$  is iid and drawn from extreme value distribution, then the probability that a given individual  $n$  – with endowed values of  $\mathbf{d}_n$  and  $\boldsymbol{\nu}_n$ , or equivalently with a *given value of*  $\mu_{njt}$  – chooses product  $j$  has the usual logit form given by  $s_{njt} = \exp(\delta_{jt} + \mu_{njt}) / \sum_{j=0}^J \exp(\delta_{jt} + \mu_{njt})$ . Integrating this individual probability over a distribution of  $\mathbf{d}_n$  and  $\boldsymbol{\nu}_n$  recovers the market share of product  $j$ .

To obtain the model predicted market shares, we use census data and randomly select 30 children and 10 adults from each MSA and year and record their vector of demographics  $\mathbf{d}_n$  (income, income square, age and gender) to construct a non-parametric distribution for  $F_d(\mathbf{d})$ . Next, for  $F_\nu(\boldsymbol{\nu})$ , we use a multivariate normal distribution and numerically compute the market share via the smooth simulator. Specifically, given  $N_s = 40$  random draws for  $(\boldsymbol{\nu}_n, \mathbf{d}_n)$  for each market  $t$ , and an initial guess of mean utility and parameters  $\boldsymbol{\theta}_2 = \{\boldsymbol{\Pi}, \boldsymbol{\Sigma}\}$ , model predicted market share  $\tilde{s}_{jt}$  is obtained as

$$\tilde{s}_{jt} = \int_{A_{jt}} s_{njt} dF_d(\mathbf{d})dF_\nu(\boldsymbol{\nu}) = \frac{1}{N_s} \sum_n^{N_s} s_{njt} = \frac{1}{N_s} \sum_n^{N_s} \left\{ \frac{\exp(\delta_{jt} + \mu_{njt})}{\sum_{j=0}^J \exp(\delta_{jt} + \mu_{njt})} \right\}. \quad (10)$$

The model parameters  $(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2)$  are estimated using Berry's two step GMM method. Briefly, given the random draw and starting values of  $\boldsymbol{\theta}_2$ , first we obtain an estimate of the mean utility  $\delta_{jt}$  via the contraction mapping

$$\boldsymbol{\delta}_t^{h+1} = \boldsymbol{\delta}_t^h + [\ln(\mathbf{s}_t) - \ln(\tilde{\mathbf{s}}_t)] \quad (11)$$

that matches model predicted market shares  $\tilde{s}_{jt}$  with the observed shares  $s_{jt}$  for each market. Next, we define the error term as  $\boldsymbol{\xi}(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2) = \widehat{\boldsymbol{\delta}}(\mathbf{s}, \boldsymbol{\theta}_2) - \mathbf{X}\boldsymbol{\theta}_1$ , and given a suitable matrix of instrumental variables  $\mathbf{Z}$ , search for values of  $(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2)$  that minimize the GMM objective function

$$\boldsymbol{\xi}(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2)' \mathbf{Z} \boldsymbol{\Phi} \mathbf{Z}' \boldsymbol{\xi}(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2) \quad (12)$$

where  $\boldsymbol{\Phi}$  is the GMM weighting matrix. The process is then repeated by computing new values of individual and model predicted market shares. We implement the algorithm following [Nevo \(2000b\)](#) and the computer code given therein.<sup>7</sup>

The price elasticities of market shares are also numerically estimated as

$$\eta_{jkt} = \frac{\partial s_{jt}}{\partial p_{kt}} \frac{p_{kt}}{s_{jt}} = \begin{cases} -\frac{p_{jt}}{s_{jt}} \int_{\mathbb{A}_{jt}} \alpha_n s_{njt} (1 - s_{njt}) dF_{\mathbf{d}}(\mathbf{d}) dF_{\boldsymbol{\nu}}(\boldsymbol{\nu}) & \text{if } j = k, \\ \frac{p_{kt}}{s_{jt}} \int_{\mathbb{A}_{jt}} \alpha_n s_{njt} s_{nkt} dF_{\mathbf{d}}(\mathbf{d}) dF_{\boldsymbol{\nu}}(\boldsymbol{\nu}) & \text{otherwise.} \end{cases} \quad (13)$$

**Instruments Matrix.** The instrument for price, as before, is the Hausman instrument and this variable and the brand characteristics (or brand dummies if instead they are used) form the main elements of the instruments matrix  $\mathbf{Z}$  as the set of exogenous variables. Note however that the exogenous brand characteristics (or dummies if they were part of  $\mathbf{X}$ ) plus the one additional instrument for price will give exactly as many moment conditions as the number of components of the parameter vector  $\boldsymbol{\theta}_1$ . These would be enough in the linear logit case. However, in the random coefficients case, we have to estimate additional  $k \times D + k \times k$  parameters of  $\boldsymbol{\theta}_2 = \{\boldsymbol{\Pi}, \boldsymbol{\Sigma}\}$  where, in our case,  $D = 4$  is the number of person specific observed characteristics, and  $k = 7$  is the length of person specific shock for each observed product characteristic (i.e. the product characteristics with random coefficients).<sup>8</sup> Estimating these additional parameters is not possible unless we have additional  $k \times D + k \times k$  moment conditions (see [Moon et al., 2014](#)). Since these additional parameters are due to the  $\boldsymbol{\mu}_n(\cdot) = \mathbf{X}(\boldsymbol{\Pi} \mathbf{d}_n + \boldsymbol{\Sigma} \boldsymbol{\nu}_n)$  term in the utility function, and involve interactions of the product characteristics with individual specific terms  $\mathbf{d}_n, \boldsymbol{\nu}_n$ , we use the average over  $N_s$  individuals of these interaction terms as additional variables in the instruments matrix  $\mathbf{Z}$ .

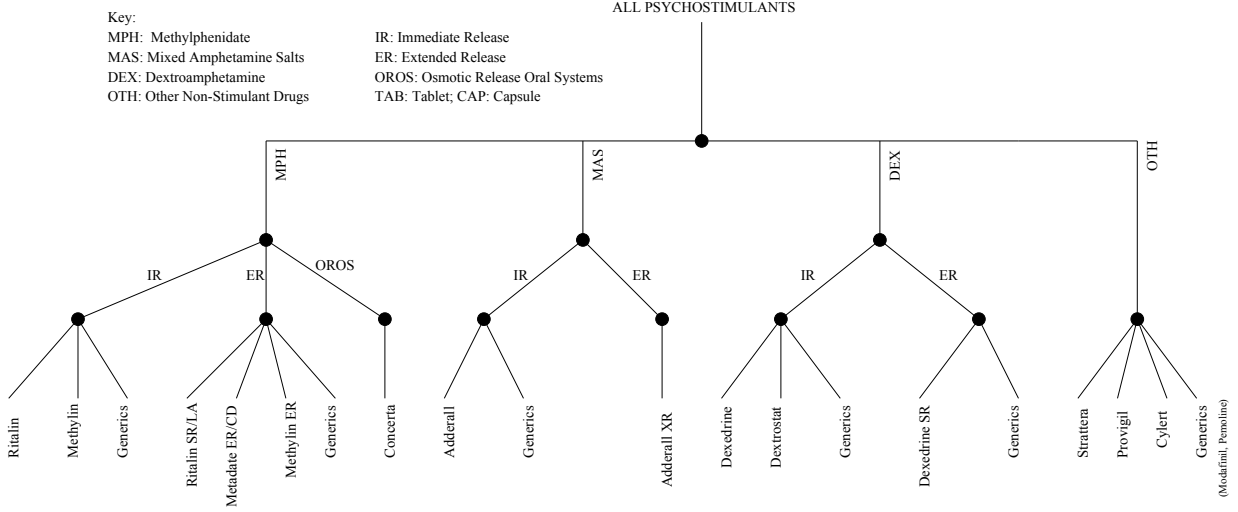

**3.4. Model 3: Multistage Budgeting and AIDS.** We can model a multistage budgeting system for a representative consumer to estimate a demand system for the drugs as follows.<sup>9</sup> At the top level (level 4), a representative patient decides how many units of ADHD drugs to consume as a

<sup>7</sup>As pointed out in [Nevo \(2000b\)](#), the matrix  $\mathbf{X}$  consisting of price and product characteristics enters the model twice, once linearly via the term  $\delta(\cdot)$ , which is common to all individuals, and second time non-linearly via  $\mu(\cdot)$  that allows for random coefficients for product characteristics. Thus,  $\mathbf{X}$  in each part can be written as  $\mathbf{X}_1$  and  $\mathbf{X}_2$ , and these need not be the same set of variables. We set  $\mathbf{X}_1$  as price and brand dummies, and  $\mathbf{X}_2$  as price and product characteristics.

<sup>8</sup>In general if we set some of the terms of the  $\boldsymbol{\Pi}$  matrix to be zero, and also set the parameter matrix  $\boldsymbol{\Sigma}$  to be diagonal, it reduces the need for additional moment conditions from  $kD + k^2$  to  $g + k$  where  $g$  is the number of non-zero terms in  $\boldsymbol{\Pi}$ .

<sup>9</sup>The multilevel AIDS model with ADHD data was estimated in [Bokhari and Fournier \(2013\)](#), and we use the parameter estimates provided therein. Here we keep estimation details to a minimum, and refer an interested reader to the given citation.

function of a price index for these drugs, her income and other demographics. At the next stage down (level 3), budget is allocated to choice of the four molecules. The next level further allocates the budget to the choice of the forms, and at level 1 the consumer chooses among specific brands or generics within each molecule and form, conditional on the budget for the segment (see Figure 1).

**Note:** Generics refer to several manufacturers for each molecule and form given in the column. There are no generic versions of Concerta and Adderall XR during the study period.

FIGURE 1. Multilevel Budgeting

Specifically, if there are  $M$  molecules indexed by  $m$ , then within a molecule there are  $F_m$  forms indexed by  $f_m$ , and for a given molecule and form there are  $J_{f_m}$  drugs indexed by  $j_{f_m}$  such that  $\sum_m^M \sum_{f_m}^{F_m} \sum_{j_{f_m}}^{J_{f_m}} j_{f_m} = J$  is the total number of drugs (since we are describing a different demand model here, some of the notation will be recycled, and should not be confused with its earlier use in the discrete choice models discussed earlier). Then the system of demand equations for each level are

$$\begin{aligned}
 \text{Level 4:} \quad & \ln Q_t = A + B \ln(I_t) + G \ln P_t + \mathbf{x}_t \boldsymbol{\lambda} + \zeta_t \\
 \text{Level 3:} \quad & \ln(Q_{mt}) = A_m + B_m \ln(y_t) + \sum_{m'}^M \Gamma_{mm'} \ln P_{nt} + \mathbf{x}_{mt} \boldsymbol{\lambda}_m + \xi_{mt} \\
 \text{Level 2:} \quad & u_{f_{tm}} = a_{f_m} + b_{f_m} \ln\left(\frac{y_{f_{tm}}}{P_{f_{tm}}}\right) + \sum_{f'}^{F_m} g_{ff'} \ln P_{f'_{tm}} + \mathbf{x}_{f_{tm}} \boldsymbol{\lambda}_{f_m} + \mu_{f_{tm}} \\
 \text{Level 1:} \quad & s_{j_{f_{tm}}} = \alpha_{j_{f_m}} + \beta_{j_{f_m}} \ln\left(\frac{y_{j_{f_{tm}}}}{P_{j_{f_{tm}}}}\right) + \sum_{j'}^{J_{f_m}} \gamma_{jj'} \ln p_{j'_{f_{tm}}} + \mathbf{x}_{j_{f_{tm}}} \boldsymbol{\lambda}_{j_{f_m}} + \varphi_{j_{f_{tm}}}.
 \end{aligned} \tag{14}$$

Level 1 equations are in AIDS specification where  $s_{j_{f_{tm}}}$  is the (revenue) share of drug  $j$  in segment  $f_m$  in market  $t$ ,  $\ln p_{i_{f_{tm}}}$  is the log price of  $i$ th drug in  $f_m$  and  $y_{f_{tm}}$  and  $P_{f_{tm}}$  are the total expenditures

and a price index for the segment. Similarly,  $\mathbf{x}_{jt_{fm}}$  and  $\varphi_{jt_{fm}}$  represent other exogenous variables and the error term that effect the shares of the drug. The next level up is also an AIDS specification where  $u_{ft_m}$  is the share of the form  $f$  in molecule  $m$  in market  $t$ . Other variables have similar interpretations where, note that the ‘price’ of form within a molecule (the term  $\ln P_{f't_m}$ ) is the same as the price index for that form in level 1 equation, and that the right hand side now includes a price index for the molecule (i.e., the  $P_{mt}$  term). Level 3 is specified as Cobb-Douglas demand equations where ‘price’ of the molecule is the price index used at the previous level. Finally at the top level, log quantity of all ADHD drugs is a function of the price index for these drugs, total income and other demographic variables.

At each level the price index is constructed as the Stone price index, i.e., a share weighted average of log price rather than Deaton and Muellllbaur’s exact price.<sup>10</sup> Thus at the bottom level, the index for the price of molecule-form  $fm$  is computed as  $\ln P_{f_{mt}} = \sum_j^{J_{fm}} s_{jt_{fm}} \ln p_{jt_{fm}}$ .

The set of equations above also include exogenous variables that may effect shares or total quantity. These are state fixed effects, time trends (up to cubic terms), (log of) number of children, number of physicians, state level medicaid enrolles, and state medicaid expenditures on drugs. Each segment is a system of equations and is estimated separately. At the lowest two levels, homogeneity, symmetry and adding-up restrictions are imposed. In total there are five bottom level segments with two or more drugs in them. At the next level up there are three separate segments with multiple equations. For instance within the MPH segment, three equations are for IR, ER and XR while within MAS there are just two equations. At the next level there is just one segment with four equations (one for each molecule) and finally at the top level there is a single equation. The equations were estimated using OLS and 3SLS where in the later case, prices are treated as endogenous. The instrument used for prices (price from other markets) is the same as that used in the earlier specified discrete choice models.

Based on estimated parameters, cross-price elasticity between two drugs  $i$  and  $k$  in molecule-form segments  $f_m$  and  $f'_{m'}$  respectively are given by

$$\begin{aligned} \frac{\partial \ln Q_{i_{f_m}}}{\partial \ln P_{k_{f'_{m'}}}} &= \left(1 + \frac{\beta_{i_{f_m}}}{s_{i_{f_m}}}\right) \bar{s}_{k_{f'_{m'}}} \left[ \frac{g_{ff'_{m'}}}{u_{f_m}} + \bar{u}_{f'_{m'}} \right] \cdot \delta_m^{m'} \\ &+ \left(1 + \frac{\beta_{i_{f_m}}}{s_{i_{f_m}}}\right) \bar{s}_{k_{f'_{m'}}} \left[ \frac{b_{f_m} \bar{u}_{f'_{m'}}}{u_{f_m}} + \bar{u}_{f'_{m'}} \right] \Gamma_{mm'} + \frac{1}{s_{i_{f_m}}} \left\{ \gamma_{ik_{f'_{m'}}} - \beta_{i_{f_m}} \bar{s}_{k_{f'_{m'}}} \right\} \cdot \delta_{f_m}^{f'_{m'}} - \delta_{i_{f_m}}^{k_{f'_{m'}}} \end{aligned} \quad (15)$$

<sup>10</sup>Note however that by using the Stone price index, even if the original prices were not endogenous, we are introducing an artificial endogeneity, as equation (14) now involves shares on both the left and right hand side of the equation. This is easily overcome by using period specific average value of shares from each county (average is over counties) to construct the price index for market  $t$ . To be clear, right hand side in the Stone price index uses  $\bar{s}_{j_{f_m}}$ , i.e., period specific average share so that each time period has a different value, but is the same for all counties. Higher level price indexes are constructed the same way.

where  $\delta_a^b$  is the Kronecker delta function equal to 1 if  $a = b$  and 0 otherwise.

#### 4. RESULTS

**4.1. Regression Coefficients.** Table 2 shows the coefficients associated with the price variable from discrete choice models ( $\alpha$  and  $\alpha_n$ ). The first three columns show the price coefficient from simple logit. All three specifications include time, time square, state fixed effects and log of number of children and log of number of physicians in the area (county) as well as state medicaid expenditures on medication and total number of enrollees in medicaid (both in logs). Specifications (1) and (2) are OLS results but in (1) we use drug characteristics (molecule and form of the drug) while in (2) we instead use brand dummies. Use of brand dummies nearly doubles the value of the price coefficient. Specification (3) uses brand dummies and instruments for price and once again the coefficient nearly doubles from its previous value.

TABLE 2. Price Coefficients from Discrete Choice Models

Logit			Random Coefficients Logit (4)					
(1)	(2)	(3)	$\theta_1$	$\theta_2$ (Interactions with Demographic Variables)				
	$\alpha$		$\alpha$	$\sigma$	Income	IncomeSq	Age	Gender
-2.076	-4.259	-8.753	-9.441	0.003	0.274	0.099	0.146	-4.087
(0.067)	(0.080)	(0.155)	(0.559)	(0.070)	(0.316)	(0.085)	(0.089)	(1.109)

**Note:** Table shows coefficients associated with price from simple logit (1,2,3) and random coefficients logit model (4). (1) is OLS without brand dummies, (2) is OLS with brand dummies, (3) is instrumental variables and brand dummies. Standard errors are in parenthesis below the coefficients. Price coefficients in this table are when price is in \$100 per DMD, i.e., divided by 100, as some scaling was necessary to overcome convergence issues in estimating the random coefficients logit model.

This general increase in the magnitude of the price coefficient is consistent with several previous studies that show a similar effect of including brand dummies and use of instruments (see for instance [Nevo \(2001\)](#), [Petrin \(2002\)](#)). Specification (4) with random coefficients shows further increase in the mean value of the price coefficient (-9.441) with dispersion of the price coefficient across individuals, but only the interaction with age and gender are significant (statistical significance of the age interaction term is weak but with gender, coded as equal to one for male, is quite strong). This model uses the Hausman instrument for prices and includes both the brand dummies and drug characteristics.

While the price coefficients across these discrete choice models can be compared, it is not possible to directly compare them to a similar set of coefficients from the multistage AIDS specifications as there is no one price coefficient to compare them to (each equation within each segment has several

price coefficients (the terms  $\gamma_{jifm}, g_{fhm}$  etc. in equations (14)). Nonetheless, we provide below coefficients on the price and segment expenditure variables from one specific middle level segment – level 2, the three forms within molecule MPH – as estimates from this segment best highlight the important differences across discrete choice models when compared to product space models. To be clear, the selected segment is MPH and the set of three share equations  $u_1, u_2$  and  $u_3$  are for shares of MPH-IR, MPH-ER and MPH-XR (i.e., the 4-hr, 8-hr and 12-hr drugs respectively) within the methylphenidate class. Together they form a system of equations that can be estimated jointly via SUR or 3SLS, and with or without any restrictions implied by micro theory (adding up, homogeneity and symmetry).

TABLE 3. Selected Regression Coefficients for MPH Segment

	(i)			(ii)			(iii)		
	$u_1$	$u_2$	$u_3$	$u_1$	$u_2$	$u_3$	$u_1$	$u_2$	$u_3$
$\ln(y/P)$	-0.029 (.002)	-0.006 (.002)	0.036 (.003)	-0.016 (.005)	0.006 (.004)	0.010 (.007)	-0.024 (.003)	-0.001 (.002)	0.025 (.004)
$\ln p_1$	-0.007 (.018)	0.01 (.017)	-0.003 (0.023)	-0.182 (.170)	-0.008 (.154)	0.191 (.251)	-0.365 (.135)	-0.170 (.048)	0.536 (.118)
$\ln p_2$	-0.044 (.022)	-0.061 (.021)	0.105 (0.028)	-0.032 (.085)	-0.136 (.077)	0.168 (.126)	-0.170 (.048)	-0.246 (.040)	0.416 (.057)
$\ln p_3$	0.078 (.019)	0.032 (.018)	-0.11 (0.024)	0.794 (.173)	0.610 (.157)	-1.40 (.255)	0.536 (.118)	0.416 (.057)	-0.952 (.126)

**Note:**  $u_1, u_2, u_3$  are share equations for MPH-IR, MPH-ER and MPH-XR respectively and  $p_1, p_2, p_3$  are prices of these three forms. Standard errors are in parenthesis. Specification (i) is SUR and does not impose homogeneity or symmetry restrictions, (ii) is GMM/IV and does not impose homogeneity or symmetry restriction and (iii) is GMM/IV and imposes both sets of restrictions. All regressions include state dummies, variable for time and time square plus additional variables at area level.

Results are summarized in Table 3. The first set of estimates for the three forms are under the columns marked as (i) and are from SUR estimation and without imposing any cross-equation restrictions. The second group of estimates (under ii) are estimated via 3SLS estimator but without imposing any restrictions. The final and preferred set of estimates (labeled iii) additionally impose homogeneity and symmetry restrictions.

The most striking result in this table is the negative coefficient on price of MPH-ER ( $p_2$ ) in the equation for MPH-IR and the coefficient on price of MPH-IR ( $p_1$ ) in the the equation for MPH-ER (for instance, in specification (iii) these are -0.170 and significant) implying that these forms are complements rather than substitutes. By comparison, both forms are substitutes for the third form

MPH-XR, and in turn that form is a substitute for each of these first two forms (positive coefficients of 0.536 and 0.416 respectively). Since the dependent variables in each of these equations are relative shares, and not log quantities, the coefficients cannot be interpreted as elasticities. Table (4) gives the conditional (level 2) elasticities for this segment, which shows the complementarity between IR and ER drugs, and are calculated from the estimates from 3SLS with restrictions.

TABLE 4. MPH Elasticities

	(A)	(B)	(C)
(A) MPH-IR	-1.97	-0.49	1.54
(B) MPH-ER	-0.94	-2.34	2.28
(C) MPH-XR	1.02	0.84	-2.92

Our conjecture is that the complementarities arise because the 4-hr and 8-hr drugs can be used in combination within a day to provide a day long coverage: a child can be given an 8-hr medication to last them through the school and then be given an additional dosage in early evening to provide coverage for the rest of the day. Taken together the two form a substitute group for the more expensive day long 12-hr drug (i.e., Concerta). This general sign pattern – complementarities between MPH-IR and MPH-ER and substitution with MPH-XR – is robust across a number of alternative specifications (and is reported elsewhere, see [Bokhari and Fournier \(2013\)](#)). We explore the implications of these negative coefficients in the MPH segment by estimating and comparing substitution patterns across all drugs in the next section.

**4.2. Substitution Patterns.** Tables (5) provides average values of own- and cross-price elasticities of the first 11 drugs based on estimates for the discrete choice models (3) and (4), and where the average is over the 778 markets. Elasticities from the multinomial logit are given in the top part of the table. Since for the logit model, cross-price elasticity for a given drug with respect to the price of any other drug is the same across all drugs (due to the IIA property), for this model we do not list the full matrix, but rather just two rows showing the own- and cross-price elasticity for each drug. The lower part of the table lists elasticities from the random coefficients logit model, including all the cross-price elasticities as they are not the same with respect to other drugs.

In the class of discrete choice logit models, the price coefficient  $\alpha$  increased across the four specifications from -2.08 in specification (1) to -9.46 in specification (4). Consequently, the magnitudes of own- and cross-price elasticities also increase across these models. Further, model (4) overcomes the IIA limitation, leading to generally much higher cross-price elasticities within a molecule-form class when compared to the simple logit models with homogenous taste parameters. The substitution patterns in (4) seem reasonable to the extent that the degree of substitutability is higher within

the same molecule-form class than across the class. Nonetheless, by construction all products are substitutes since the model does not allow for complementarities.

By contrast, Table (6) lists the the substitution patterns corresponding to the multilevel AIDS model described earlier. Observe that across the two types of models (random coefficients vs nested AIDS), the own-price elasticity magnitudes decrease but the cross-price elasticity magnitudes generally increase quite dramatically. Moreover, several of the cross-price elasticities, especially those for drugs in the MPH-IR and MPH-ER segments are negative. The source of these negative cross-price elasticities is due to the complementarities in the MPH segment noted earlier.

**4.3. Merger Simulations.** To understand how important the differences in the estimated substitution patterns can be in the context of competition economics, we compare predicted percentage

change in prices of all drugs under three hypothetical mergers but based on elasticity estimates from the last three models, i.e. simple logit, random coefficients logit, and nested AIDS models.

In the first hypothetical merger case, Novartis merges with Mallinckrodt. Novartis produces a 4-hr and a 8-hr variant of Ritalin, which is an established and well known brand, while Mallinckrodt competes with Novartis in both of these subsegments. Nonetheless, the market share by value of each of these firms in 2003 is small (Novartis is 3.57% and Mallinckrodt is 1.9%) and would not necessarily draw major scrutiny from competition authorities. For the second hypothetical merger, we consider a medium size merger, where Novartis with its small market share merges with Alza with 26.10% share for its product Concerta. At the time, Alza was the only company selling the 12-hr variant of the MPH molecule but it had no products in the competing segments of 4-hr and 8-hr drugs within this molecule. Hence we consider a merger between Alza in the 12-hr segment in MPH with Novartis providing 4-hr and 8-hr drugs. Such a merger would likely draw some attention from competition authorities and invoke further investigation. The third and last hypothetical merger we consider is between Alza and Shire. The market share of Shire through its three products in competing molecule class of MAS and DEX was 26.89%. Also, Shire was the only other firm

producing a day-long drug, Adderall XR, albeit for a different molecule than Concerta. A proposed merger between two largest firms would definitely be investigated by the competition authorities.

Our merger simulations are based on a Nash-Bertrand price competition model in the context of multiproduct firms, where based on an estimated demand model, we first back out marginal costs via an equilibrium price equation, and then use these costs to compute new prices under joint profit maximization of co-owned products of the merging firms (see [Nevo, 1998](#)). To be clear, let there be  $J$  related products where the unconditional demand for product  $j$  is given by

$$Q_j = D_j(p_1, \dots, p_J, Z) \quad (16)$$

and where  $Z_j$  represents exogenous demand shift variables. If there are  $L$  firms, and the  $l$ th firm produces a subset  $\mathfrak{L}_l$  of the products, then it maximizes over the sum of profits associated with each products as

$$\Pi_l = \sum_{r \in \mathfrak{L}_l} (p_r - c_r) D_r(p_1, \dots, p_I, Z)$$

where  $c_r$  is the constant marginal cost. Under Nash-Bertrand price competition, price  $p_j$  of any product  $j$  produced by firm  $l$  satisfies the first order conditions

$$Q_j + \sum_{r \in \mathfrak{L}_l} (p_r - c_r) \frac{\partial D_r(p_1, \dots, p_I, Z)}{\partial p_j} = 0. \quad (17)$$

If we let  $\Theta$  be a  $1/0$  matrix with ones in the leading diagonal and in locations where a firm jointly produces products  $r$  and  $j$  and define  $\Omega$  such that  $\Omega_{jr} = -\Theta_{jr} \frac{\partial D_r(p_1, \dots, p_J, Z)}{\partial p_j}$ , then the first order conditions imply a price equation (in matrix notation) of the form

$$p = c + \Omega^{-1} Q(p_1, \dots, p_J, Z). \quad (18)$$

For each of the three models, we proceed as follows. Using demand parameters and data from 2003, and the actual ownership matrix  $\Theta$ , we back out the marginal cost for each product in each market using equation (18) above. This calculation involves solving 17 linear equations in each market. Next, change the ownership matrix to match one of the three hypothetical mergers given above. Based on the estimates of marginal costs and the new ownership matrix, solve for new equilibrium prices in each market per equation (18) again. Since the markup term  $\Omega^{-1} Q(p_1, \dots, p_J, Z)$  is also a function of the price vector, this requires solving a non-linear system of 17 equations per market.<sup>11</sup>

<sup>11</sup>If the demand system is linear, these equations also become linear as then the slope matrix  $\frac{\partial D_r(\cdot)}{\partial p_j}$  is not a function of prices. For the multilevel AIDS model, we took advantage of this simplification by assuming that the overall unconditional demand system is locally linear. Then by using the mean prices and shares/quantities in 2003, we converted the unconditional elasticity matrix from multilevel AIDS model given in table [Table 6](#) to obtain estimates of intercepts and slopes for the linear demand system. By using this simplification, it primarily allows us to avoid predicting quantities and relative and absolute shares (at incremental price vector) using large number of demand equations associated with the multilevel AIDS system. We further verified that this simplification does not lead to any major differences in the final results by subjecting the other two models to the same linear simplification, i.e., by backing intercepts and slopes for the unconditional demand system by staring out with the elasticity matrix from the other two models. The merger simulations results for the logit and random coefficients

TABLE 7. Three Hypothetical Mergers

	Average (Weighted)			0.02	0.02	0.49	0.10	0.11	2.62	0.91	0.83	3.91

The results of hypothetical mergers, i.e., predicted percentage change in price per the three different demand models, are summarized in Table (7). Under each merger, the logit model predicts very small changes in the price of the drugs of the merging companies, and almost none in the price of all other products. By comparison, the random coefficients model predicts slightly larger changes in the prices of the drugs of the merging companies, but to some extent also in the prices of the drugs by the non-merging companies. In terms of overall average price changes (weighted by share of sales pre-merger) the percentage change across the two models is very similar. However, the predicted price changes are significantly much larger for the multilevel AIDS model, not only for the drugs of the merging companies but also of other drugs with the share weighted average ranging from 0.49 for the first (small) merger to 3.91 for the third (large) merger. Under the third demand model the predicted price changes of the merging parties as well as of the competitors are both large.

---

models were very similar to when we use the correct non-linear system implied by the equation above or via this linear unconditional demand. There were some additional (minor) changes made to the multilevel AIDS elasticity matrix for the merger analysis. They do not change the main conclusions of this section and are described in the appendix.

---

While predicted price changes are unlikely to be the only factor a competition authority would consider when deliberating a merger, nonetheless, these examples show that multilevel AIDS model can give much larger estimates.

## 5. CONCLUSION

Our analysis shows that discrete choice models can underestimate the predicted changes in prices in merger simulations, both for the merging parties as well as for the competitors. This result is driven both by the magnitude and sign of cross-price elasticities. Discrete choice models cannot, without some additional information, account for underlying complementarities which may be important in some industries. On the flip side however, the magnitude of the cross-price elasticities can be too ‘large’, in the sense that they may lead to the failure of second order conditions for profit maximization not holding in merger simulations. This can happen for instance when the sum of the cross-price elasticities is larger than the own-price elasticities, and the ownership matrix also mostly consists of ones in the off-diagonals (this potential problem does not occur in logit or random coefficients models).

The results of this paper are meant to serve as a cautionary tale when using discrete choice models, and not an overall indictment against them. As documented earlier, the data requirements for estimating product space models are substantial and practical limitations may still favor the use of discrete choice models. Nonetheless, estimates from these models should be taken as a lower bound to the predicted price changes, and if there is any reason to suspect that some of the products may be complements, effort should be directed to acquiring better data to allow for estimation in product space.

## APPENDIX

**Simulation Details.** The elasticity matrix for the multilevel AIDS was modified in three ways before using it for merger analysis. First, if the cross-elasticity estimate was not statistically significantly different from zero, then we set it to zero before the merger analysis. This did not change the results in any appreciable manner for the mergers considered here, except that price changes in the third merger were even larger with average price change being 5.10% instead of 3.91% as reported in the paper. Second, the own-price elasticity of drug (2), Methylin by Mallinckrodt, was estimated to be in the inelastic region ( $\eta_{2,2} = -0.64$ ). Using this estimate as is, leads to negative estimates of marginal costs for this drug. Since it is otherwise very similar to generic versions of MPH-IR, and indeed itself is almost a generic in terms of brand recognition and prices, we assumed that its marginal cost would be similar to that of the other generics in this segment. Hence to overcome this difficulty, we set its own-price elasticity to be the same as that of generic MPH-IR.

This modification leads to some modest differences in merger predicted prices, particularly in the first hypothetical merger case as it involves merger between this firm and Novartis. Overall average price change is only 0.16% for the first merger (instead of 0.49% as reported in the paper) if we do not make change. Third, we set the cross-price elasticity of drug (17) to zero. If we do not make this change (but continue to make the other two changes), results for average percentage change in prices are even larger than those reported in the paper for all three mergers. This change was necessary because, as documented in [Bokhari and Fournier \(2013\)](#), demand for this last drug is measured very imprecisely and small changes in the underlying model specification change the cross-price elasticity for this drug with the other 16 drugs substantially. Thus we set the off-diagonal in the elasticity matrix associated with drug 17 to zero so that when the Nash-Bertrand equilibrium prices are computed for the remaining 16 drugs under a merger scenario, the cross-effects with drug 17 would not impact those calculations. Consequently, the price change in drug 17 is also zero under all three scenarios.
